Abstract. We directly measured the s -wave scattering cross-section of ultracold ^{40}K atoms across the 20.2 mT Feshbach resonance by colliding pairs of degenerate Fermi gas (DFG) clouds and imaging the scattered atoms. Owing to DFG's low density, few atoms scattered, even near the resonance. To optimize signal to noise, we developed techniques to interpret absorption images in the regime where recoil induced detuning corrections are significant. By applying these techniques to our s -wave scattering data we extracted the resonant magnetic field value $B_0 = 20.247(2)$ mT and resonance width $\Delta = 1.0(1)$ mT. These imaging techniques are generally applicable to experiments requiring accurate interpretation of absorption images with a wide dynamic range of atomic densities.

1. Introduction

Feshbach resonances are widely used for tuning the interaction strength in ultracold atomic gases. They have been particularly instrumental in the study of interactions and interaction-dependent processes in cold Fermi gases. In contrast to atomic Bose-Einstein condensates (BECs), where even weak interactions play a crucial role, for example giving rise to their characteristic Thomas-Fermi density profiles [26], the effects of interactions in Fermi gases are harder to observe. The density of Fermi clouds is typically ~ 1000 times less than that of BECs, making it necessary to enhance the strength of interactions in order to observe them [13]. The tunability of interactions provided by Feshbach resonances has allowed for creation of molecular Bose-Einstein condensates from Fermi gases [9, 12, 29] as well as observation of the phase transition from the BCS to BEC regime at sufficiently low temperatures [1, 3, 22, 30].

A Feshbach resonance occurs when a two-atom bound molecular state energetically approaches the two-atom continuum [4, 25]. In experiment, the relative energy of the free atomic states and the molecular state is defined by a bias magnetic field, so the Feshbach resonance can be approached by changing the bias field. In the simple case where there are no inelastic two-body channels, such as for the ^{40}K resonance discussed in this work, the effect of the resonance on the scattering length between two free atoms is [4]

$$a(B) = a_{bg} \left(1 - \frac{\Delta}{B - B_0} \right), \quad (1)$$

a_{bg} is the background scattering length, Δ is the width of the resonance, and B_0 is the field value at which the resonance occurs. The scattering length diverges at the resonance.

The exact value of the resonant field B_0 is difficult to calculate analytically and is commonly computed via numerical models based on experimental input parameters [8, 17, 24] or determined experimentally [5, 10]. Many experimental techniques have been used to characterize Feshbach resonances, including the observation of atom loss due to three-body inelastic scattering, measurement of re-thermalization timescales, and anisotropic expansion of the cloud upon release from a confining potential, all of which infer the elastic scattering cross section from collective behavior of the cloud [19–21].

Here we used direct scattering as a primary probe of the location and width of a Feshbach resonance. We collided pairs of ultra-cold Fermi gas clouds and directly imaged the resulting s -wave scattering halos as a function magnetic field strength. This allowed us to observe the enhancement in scattering without relying on proxy effects. We measured the fraction of atoms scattered during the collision, and from this fraction deduced the resonant magnetic field and width of the resonance.

In our dilute Fermi clouds, even with the resonant enhancement of the scattering cross section, only a small fraction of the atoms scattered as the clouds passed through each other. This made direct detection of s -wave scattering halos difficult due to detection uncertainty, that disproportionately affected regions of low atomic density in absorption images. To optimize the signal to noise for low atom numbers, we absorption

imaged with fairly long, high-intensity pulses — a non-standard regime, where the atoms acquired a velocity during imaging and the resulting Doppler-shift was non-negligible. Simulation of the absorption imaging process was necessary for an accurate interpretation of these images. With the simulation corrected images, we extracted the fraction of atoms scattered in our collision experiment.

This paper is in two parts. In the first, we study absorption imaging in the presence of a significant time-dependent Doppler shift and show how we use our results to interpret data. In the second, we describe our *s*-wave scattering experiment and extract a measure of the location and width of the Feshbach resonance in ^{40}K .

2. Absorption imaging in the presence of strong recoil induced detuning

Absorption imaging measures the shadow cast by an atomic ensemble in an illuminating probe laser beam on a camera. This imaging technique relies on optical transitions between the ground and certain excited atomic states. Such atomic transitions have an energy difference $\hbar\omega_0$, and a natural transition linewidth Γ . When interacting with a laser field an atom scatters photons from the laser field into the empty vacuum modes. The rate at which this scattering occurs, in the two-level atom approximation, is [18]

$$\gamma_{sc} = \frac{\Gamma}{2} \frac{I/I_{\text{sat}}}{1 + (2\delta/\Gamma)^2 + I/I_{\text{sat}}}, \quad (2)$$

where I/I_{sat} is the laser intensity as a fraction of the saturation intensity, and $\delta = \omega_L - \omega_0$ is the detuning, the difference between the resonant transition frequency and the frequency of the laser light.

An absorption image is obtained by shining an on- or near-resonant probe beam ($\delta \approx 0$) onto the atomic cloud. Some of the light is scattered by the atoms, and the unscattered light, $I_f(x, y)$, is imaged onto a camera, as depicted in Fig. 1a (top). The probe light is reapplied with the atoms absent to calibrate the intensity $I_0(x, y)$ of light unaffected by the atoms (bottom).

The intensity $I_f(x, y)$ is related to the number of atoms the light encountered. Consider the light as it travels along the imaging axis $\hat{\mathbf{e}}_z$ through a 3-D atomic density profile $\rho(x, y, z)$. For the purposes of this discussion, let us focus on a single pixel of the camera, and thus a single value of I_0 and I_f , and a single column of atoms, $\rho(z)$. We are not able to infer the entire atomic distribution, but for each pixel we may obtain the column density, $n = \int \rho(z) dz$. As the light travels through a column of atoms, each atom scatters light according to Eq. (2). Therefore, the atoms further along the imaging axis z experience a reduced optical intensity due to attenuation of the laser field by the other atoms (Fig. 1b). The intensity change from scattering as a function of z is

$$\frac{dI(z)}{dz} = \hbar\omega_L \rho(z) \gamma_{sc}(z) = -\rho(z) \sigma_0 \frac{I(z)}{1 + D^2 + I/I_{\text{sat}}}, \quad (3)$$

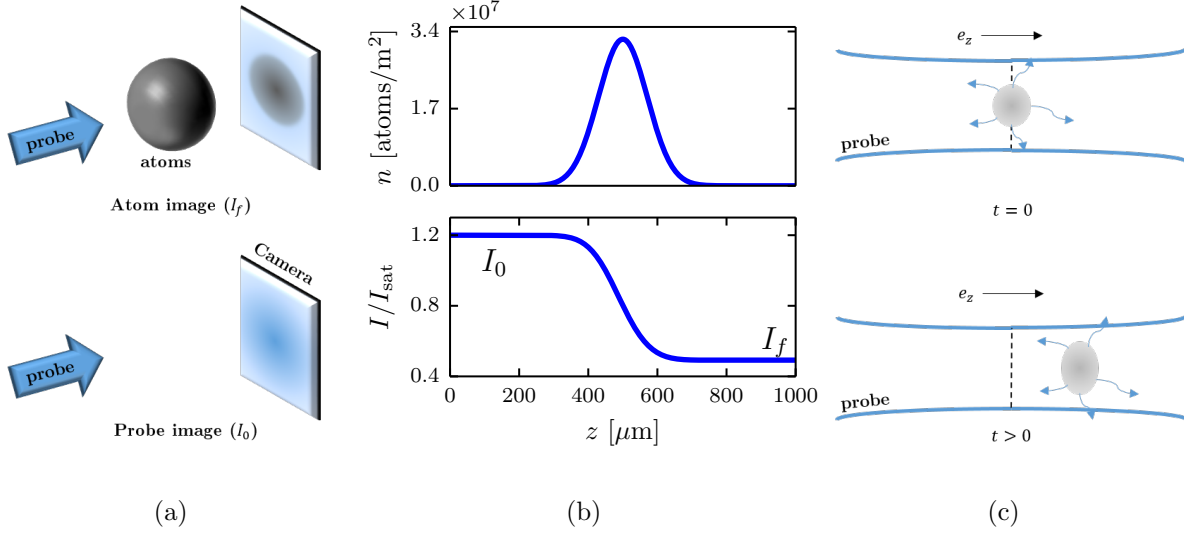

Figure 1. Absorption imaging. a. Near resonant probe light illuminates the atoms, and the transmitted light (containing a shadow of the atoms) is imaged on the camera. After the atoms depart an image of just the probe light is taken. b. The probe beam is partially absorbed as it traverses the cloud, and the intensity seen by atoms further along the imaging direction $\hat{\mathbf{e}}_{\mathbf{z}}$ is lowered. c. An atomic cloud illuminated by a probe light field absorbs photons from the probe and re-emits them in all directions. This process results in a net velocity of the cloud in the direction of the probe light as well as diffusive spreading in the transverse directions.

where σ_0 is the resonant scattering cross section and we define a scaled detuning $D = 2\delta/\Gamma$. Integrating this equation yields [23]

$$\sigma_0 n^{(1)} = - (1 + D^2) \ln \left(\frac{I_f}{I_0} \right) + \frac{I_0 - I_f}{I_{\text{sat}}}. \quad (4)$$

When the probe intensity is much smaller than the saturation intensity, $I_0 \ll I_{\text{sat}}$, the right hand side of Eq. (4) reduces to the optical depth, $OD = -\ln(I_f/I_0)$ [23]. This is the simplest possible model relating the observed intensity to the column density $\sigma_0 n$. When the probe intensity is comparable to the saturation intensity, the second term in Eq. (4) becomes significant, and we call this the column density corrected for high probe intensity $\sigma_0 n^{(1)}$.

Equations (3)-(4) neglect the atomic recoil momentum and its effect on the laser detuning [14]. When an atom absorbs a photon from the laser light field it acquires a momentum kick $\hbar k_R$ in the direction of the light field. The associated recoil velocity is $v_r = \hbar k_R/m$, where $k_R = 2\pi/\lambda$ is the recoil momentum of the light field with wavelength λ and m is the atomic mass. The re-emitted photon imparts a similar recoil momentum \vec{p}_e . Over many scattering events this momentum distribution averages to zero. Therefore the atom will acquire an average per-photon velocity v_r along $\hat{\mathbf{e}}_{\mathbf{z}}$. The variance of \vec{p}_e , however, is not zero, allowing the atoms to acquire some momentum transverse to the

laser field. We will ignore this correction, but the effect of this on the atomic cloud is pictured in Fig. 1c.

This velocity parallel the light field Doppler shifts the atoms from resonance. After scattering N photons an atom acquires an average velocity Nv_r and an additional detuning $\delta = kNv_r$. Therefore, even if the probe beam is initially on resonance with the atomic transition, we cannot neglect the detuning's effect on the scattering rate. Furthermore, this detuning varies both with imaging time t and with distance along the propagation direction z (Fig. 2a). Thus, the intensity lost to the atoms also acquires a time dependence:

$$\frac{dI(t, z)}{dz} = \sigma_0 \rho(t, z) \frac{I(t, z)}{1 + D(t, z)^2 + I(t, z)/I_{\text{sat}}}, \quad (5)$$

where, if we assume that the atoms do not move significantly within the cloud during the imaging time, the scaled detuning D can be expressed as

$$D(t, z) = \frac{2v_r}{\Gamma \hbar c \rho(t, z)} \int_0^t \frac{dI(z, \tau)}{dz} d\tau; \quad (6)$$

the relationship between the atomic density and the observed intensities is no longer straightforward.

By considering this equation perturbatively in imaging time we obtain corrections to second order [15]

$$\sigma_0 n^{(2)} = c_0 + c_1 t + c_2 t^2 \quad (7)$$

$$\sigma_0 n^{(2)} = \sigma_0 n^{(1)} + \frac{(kv_r t)^2}{3} \left[\frac{I_{\text{sat}}}{I_f + I_{\text{sat}}} - \frac{I_{\text{sat}}}{I_0 + I_{\text{sat}}} + \ln \left(\frac{I_f + I_{\text{sat}}}{I_0 + I_{\text{sat}}} \right) \right]. \quad (8)$$

As shown in Fig. 2b, the perturbative treatment is accurate to times up to the recoil time, defined as the time it would take a single atom to be detuned by half an atomic linewidth, but diverges after that point. To adequately correct for the recoil induced detuning of the atoms, we numerically simulated the imaging process to obtain I_f as a function of imaging time, atomic density, and probe intensity.

In the following, we describe two versions of this simulation. First, we took a simplistic approach where the spatial distribution of atoms did not change appreciably during the imaging time: $vt \ll I_0/(\hbar\omega_L\gamma_{sc}\rho)$. We verified this approach in known limits and then cross-checked the validity of the static assumption. For realistic input parameters, we found this assumption to be invalid. We then developed a quasi-classical approach and allowed the atoms to move during the imaging time. While the atomic trajectories were wildly different than in the static atom approximation, the predicted OD s only differed on the 0.5% level.

2.1. Stationary atom model

To solve Eqs. (5)-(6), we simulated a 1-D Gaussian density distribution $\rho(z)$. We divided the cloud into spatial bins (the bin size was decreased until the result only differed at the 10^{-5} level from smaller bin sizes). In this approximation, the number of atoms in

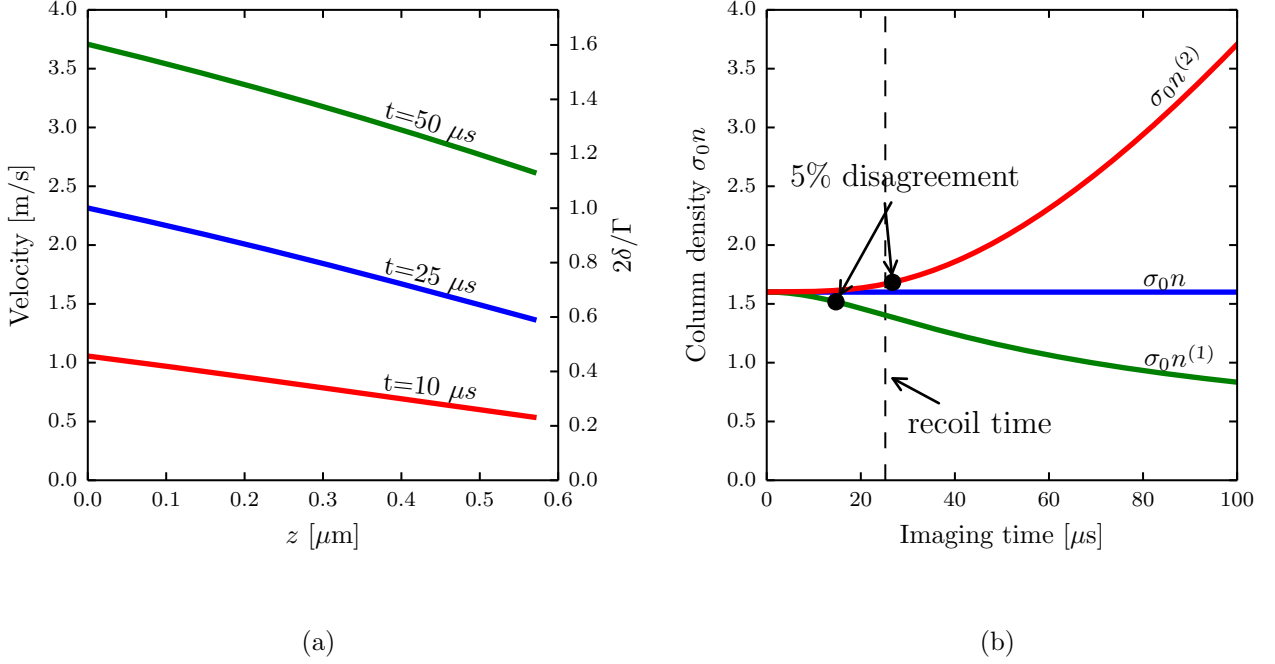

Figure 2. (a) Dependence of velocity and detuning on position simulated for ^{40}K at three different imaging times and a probe intensity $I_0 = 0.8I_{\text{sat}}$. (b) Column densities deduced from optical depths obtained from recoil detuning corrected simulation of on-resonant imaging of ^{40}K atoms at probe intensity $I_0 = 0.8I_{\text{sat}}$. The input column density $\sigma_0 n = 1.6$. $\sigma_0 n^{(1)}$ is the high probe intensity corrected optical density given by Eq. (4). $\sigma_0 n^{(2)}$ is the column density as expanded to second order in time, Eq. (8) [15].

each bin was time-independent. The algorithm used is shown in Alg. [1]. We call the optical depth simulated by this algorithm the simulated optical depth OD^{sim1}

We checked the validity of our simulation in the limits where the problem is analytically solvable. In the limit where the probe intensity is much weaker than the saturation intensity, $I_0 \ll I_{\text{sat}}$, the atoms' velocities are hardly changed, and Eq.(5) reduces to

$$\frac{dI(z)}{dz} = -\rho\sigma_0 I(z), \quad (9)$$

from which we recover the analytic form

$$\sigma_0 n^{(0)} = -\ln I_0/I_f. \quad (10)$$

In the limit where the probe intensity is much larger than the saturation intensity, $I_0/I_{\text{sat}} \gg D$, even far detuned atoms will scatter light at their maximum. The time dependence of the detuning can thus be neglected, and Eq. (5) becomes

$$\frac{dI(z)}{dz} = -\rho\sigma_0 I_{\text{sat}}, \quad (11)$$

Figure 3. Optical depth as a function of probe intensity as predicted by the simulation (blue symbols) and by Eq. (4) (green curves), for three different imaging times. The predictions agree in both the high and low intensity limits, and differ for probe intensities comparable to the saturation intensity and longer imaging times.

which integrates to

$$\sigma_0 n = \frac{I_0 - I_f}{I_{\text{sat}}}. \quad (12)$$

We recognize the right hand sides of Eq. (10) and Eq. (12) as the two terms in Eq. (4). Thus, as shown in Fig. 3, OD^{sim1} coincides with the optical depth as predicted by Eq. (4) in both the small and large probe intensity limits.

We used the results of this simulation to cross-check if the validity of the stationary atom assumption, i.e. the distance traveled by the atoms (as deduced from integrating

Figure 4. (a) Position of atoms as a function of imaging time for atoms in the first (solid green), middle (dashed red), and last (dotted blue) bins of the simulated density distribution for an initial cloud $50 \mu\text{m}$ in extent. The probe intensity used in this calculation was $1.2 I_{\text{sat}}$, and the column density was $\sigma_0 n = 1.6$. (b) The velocity of a single composite atom as a function of probe intensity for various imaging times. Simulation data (dots) and numerical solutions of Eq. (13) (lines) are in agreement.

the acquired recoil velocity over the imaging time) is less than the bin size. As can be seen from Fig. 4a, not only do the atoms travel more than the bin size, but they travel far beyond the initial extent of the cloud. Moreover, owing to the higher initial scatter rate, the back of the cloud overtakes the front for long imaging times. Thus, the atomic distribution as a function of position changes dramatically during the imaging pulse, and the stationary assumption is invalid.

2.2. Traveling atom model

To account for the changing atomic distribution during the imaging pulse, we numerically simulated the classical kinetics of atoms subject to the recoil driven optical forces. To simulate large ensembles in a reasonable time, we modeled composite ‘super-atoms’, each describing the aggregate behavior of N_{ca} atoms. The amended algorithm is shown in Alg.[2].

To validate our code, we again checked the velocity predicted in this model against known limits. One such limit is that of a single composite atom. In this case, there is

Algorithm 2 Travelling atom model

```

 $z[n] = z_0, \delta[n] = 0$  {initialize position and detuning for each composite atom, labeled by index  $n$ }
 $O[i] = n$  {make a list of composite atom indexes, ordered by position}
 $I[n = 0, t] = I_0$  {  $t$  is the time index,  $I$  is in units of  $I_{\text{sat}}$  }
 $H_f = 0$  {Radiant fluence seen by camera after passing through cloud}
for  $t = 0$  to  $t_f$  do {loop over time steps}
  for  $i = 1$  to  $N$  do {loop over superatoms}
     $n = O[i]$  {apply probe intensity to composite atoms in order of appearance}
     $A = \sigma_0 N_{sa} dz$  {dz is length over which atoms were grouped into single composite atom}
     $B = v_r dt / (\hbar c N_{sa})$  {dt is the time step}
     $I[n, t] = I[n - 1, t] - AI[n - 1, t] / (1 + \delta[n]^2 + I[n - 1, t])$  {Eq. (5)}
     $\delta[n] += B (I[n - 1, t] - I[n, t])$  {Eq. (6), detuning in units of  $\Gamma/2$ }
     $z[n] += dt \Gamma \delta / 2k$  { $k$  is the wavenumber,  $\Gamma \delta / 2k$  is the velocity at  $\delta$  detuning}
  end for
   $O[i] = \text{sort}(n, \text{key} = z[n])$  {sort composite atom indexes by current position}
   $H_f H_f + I[N, t] dt$  {collecting total fluence seen by the camera}
end for
 $OD^{\text{sim2}} = -\ln(H_f / I_0 t_f)$ 

```

no attenuation, and the intensity seen by the composite atom is constant at I_0 . Only the detuning evolves in time, and Eqs. (5) and (6) give

$$\frac{dD(t)}{dt} = k_R v_r \frac{\tilde{I}}{1 + D^2 + \tilde{I}}, \quad (13)$$

where $D = 2\delta/\Gamma$, and $\tilde{I} = I_0/I_{\text{sat}}$. Equation (13) can be solved numerically, and is in agreement with our simulation, as seen in Fig. 4b.

We used this model to study the time evolution of the cloud shape during imaging and visualized the phase space evolution of superatoms, shown in Fig. 5. The cloud is strongly distorted during the imaging time.

We compared the optical depths predicted by each of the two models, OD^{sim1} and OD^{sim2} . As seen Fig. 6a, the predicted optical depths were hardly changed by including the full time evolution: $|OD^{\text{sim1}} - OD^{\text{sim2}}| / OD^{\text{sim1}} \leq 0.005$. Thus, for the purposes of deducing the atom density from experimental optical depths, the stationary atom model is sufficient. Furthermore, we simulated a range of initial density profiles $\rho(z)$, and found their impact to be negligible – the only observable is the integrated atomic density $n = \int \rho(z) dz$. For interpreting experimental images, we used the data generated by the travelling atom simulation.

Figure 5. Phase space evolution of an atomic cloud exposed to probe light with intensity $I_0 = 1.2 I_{\text{sat}}$. We defined $\Delta v = v - \langle v(t) \rangle$, $\Delta(2\delta/\Gamma) = 2\delta/\Gamma - \langle 2\delta(t)/\Gamma \rangle$ and $\Delta z = z - \langle z(t) \rangle$, subtracting out the center of mass position, velocity and detuning of the cloud. The optical depth is 1.6, and the initial cloud is a Gaussian with a width of 10 μm in (a) and 1 μm in (b). The center of mass detunings $\langle 2\delta(t)/\Gamma \rangle$ are (0, 1.47, 2.26, 2.81, 3.23, 3.58) sequentially, and are the same for both initial cloud widths.

2.3. Signal to noise optimization

This simulation allowed us to interpret experimental data. For a given imaging time, we created a look-up table of predicted optical depth as a function of probe intensity and atomic column density. We then found the observed optical depth on this table, with the given probe intensity, and inferred the atomic density. The uncertainty in the measured intensities can be propagated through this procedure, and we established optimal imaging parameters to maximize the signal to noise ratio of this detection scheme.

The only source of measurement uncertainty we considered was the Poisson distributed photon shot noise, with a standard deviation proportional to $\sqrt{N_p}$, where N_p is the photon number. We then propagated this uncertainty through our correction scheme to obtain the uncertainty in our deduced value of $\sigma_0 n$. We define the signal to noise ratio (SNR) as $\sigma_0 n / \delta_{\sigma_0 n}$, where $\delta_{\sigma_0 n}$ is the propagated measurement uncertainty.

As seen in Fig. 7a, after about 40 μs extending the imaging time no longer yields appreciable improvement in SNR. Imaging for 40 μs as opposed to 10 μs where the

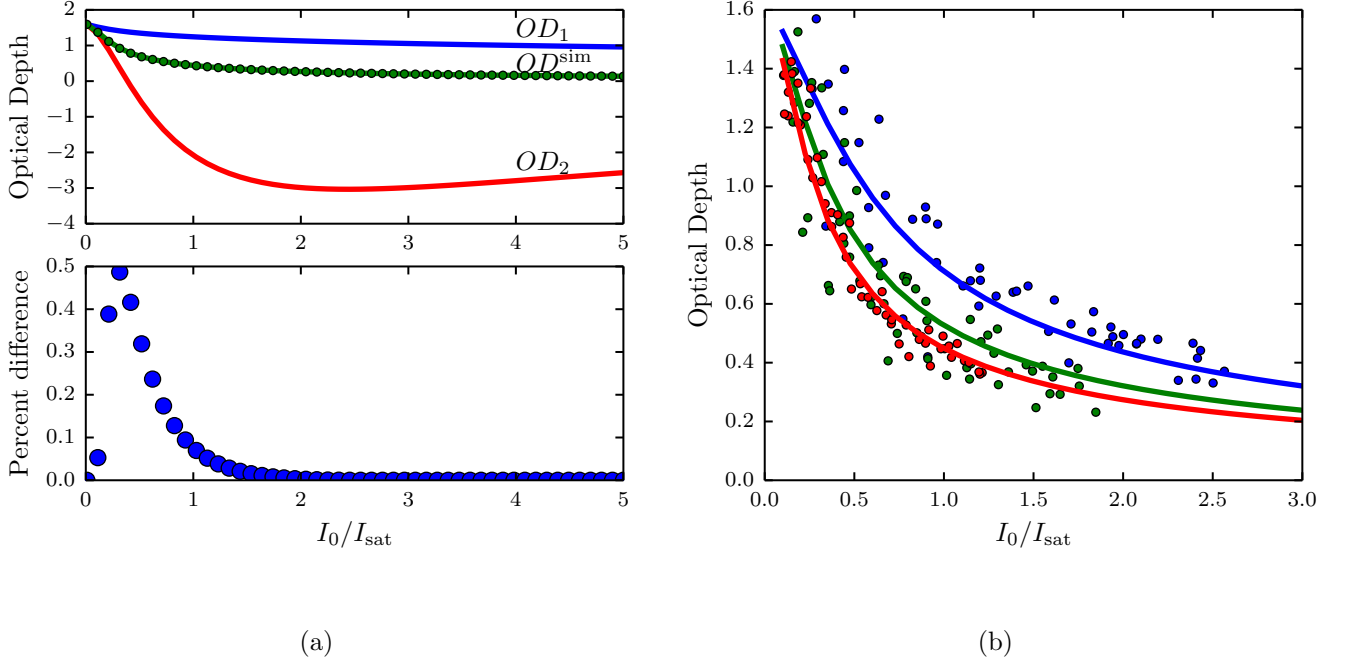

Figure 6. (a) Top. Optical depth as a function of probe intensity for an imaging time $t = 100 \mu\text{s}$. The two versions of simulated optical depth, $OD^{\text{sim}1}$ (green curve) and $OD^{\text{sim}2}$ (green dots) are plotted. Bottom. The percent difference, $100 * |OD^{\text{sim}1} - OD^{\text{sim}2}| / OD^{\text{sim}1}$, from the top graph. (b) The optical depth as a function of probe intensity for three imaging times: $t = 40 \mu\text{s}$ (blue), $t = 75 \mu\text{s}$ (green), $t = 100 \mu\text{s}$ (red). The dots represent experimental data and the lines represent the best fit of simulated data. The optimal fit parameters pictured are a $\sigma_0 n$ of 1.627(5) and saturation intensity of 29(7) counts/ μs .

uncorrected model is appropriate, improves the SNR by a factor of 1.5. We performed the experiments described in the second section at $40 \mu\text{s}$ imaging time. Figure 7b shows that the optimal probe intensity varies with the atomic column density. For low atom numbers, $\sigma_0 n \approx 0.1$, a probe intensity of $I_0 \approx 0.6 I_{\text{sat}}$ is best. However, in our experiment the probe intensity had a gaussian profile and was not uniform over the whole image. The typical probe intensities used in our experiments varied over the $I_0 = 0.1 I_{\text{sat}} - 0.7 I_{\text{sat}}$ range.

2.4. Calibration of saturation intensity

A charge-coupled device (CCD) camera was used to take the absorption images. Each camera pixel converted the photons it was exposed to, with some efficiency, into photoelectrons, and digitally returned an integer, called ‘counts’, that was proportional to the radiant fluence. However, the proportionality constant depends on many factors, such as the quantum efficiency of the camera, the electronic gain during the readout

Figure 7. Signal to noise ratio (SNR) for three different column densities after correcting for recoil induced detuning. (a) SNR as a function of imaging time for a probe intensity of $I_0/I_{\text{sat}} = 5.0$ and (b) SNR as a function of probe intensity for an imaging time of $50 \mu\text{s}$.

process, losses in the imaging system and the polarization of the probe light.

We determined this proportionality constant through direct measurement. In the limit where the system is adequately described by $\sigma_0 n = -\ln(I_f/I_0)$, only the ratio of the initial and final intensities matter, and this proportionality constant is irrelevant. In all other regimes, however, the ratio of the initial and final intensities to the saturation intensity also comes into play, making the proportionality constant significant. One way to approach this calibration is to determine the saturation intensity in units of ‘counts’ per unit time.

To calibrate the saturation intensity in camera counts per unit time, we took absorption images of ^{40}K clouds at three different imaging times ($40 \mu\text{s}$, $100 \mu\text{s}$, and $200 \mu\text{s}$) with varying probe intensities. In a small region at the center of the cloud the atomic density was approximately uniform, and we averaged the initial and final intensities of each pixel in that region. Thus, for each image we obtained I_0 and I_f , in counts per microsecond. We then simultaneously fit our simulated optical depth OD^{sim} to this full data set, with the atomic density $\sigma_0 n$ and I_{sat} in counts per microsecond as free parameters. As seen in Fig. 6b, the model produced a good fit to the experimental data, and provided a calibration of the saturation intensity for our experiment.

3. *s*-wave scattering experiment

In this section we describe our Fermi scattering experiment. We collided two counter-propagating ^{40}K clouds and observed the resulting *s*-wave halo of scattered atoms. We measured the dependence of the scattered atomic fraction on the bias magnetic field in the vicinity of the Feshbach resonance. We used this data to extract the location of the magnetic fields resonance of 20.247(2) mT and a width of 1.0(1) mT, similar to the accepted values of 20.210(7) mT and 0.78(6) mT [22].

3.1. Experimental procedure

We prepared clouds of cold ^{40}K atoms in a hybrid ^{40}K and ^{87}Rb apparatus, previously described in [11, 16, 27]. We used a Zeeman slower to sequentially slow both species before capturing in a magneto-optical trap (MOT). After 7 s seconds of MOT loading ^{40}K followed by 1.5 s of loading both ^{40}K and ^{87}Rb , we cooled both species in optical molasses for 2 ms. We optically pumped both species into their maximally stretched magnetically trappable states, $|F = 9/2, m_F = 9/2\rangle$ for ^{40}K and $|F = 2, m_F = 2\rangle$ for ^{87}Rb . Both species were then loaded into a quadrupole magnetic trap with a ≈ 7.68 mT/cm gradient along $\hat{\mathbf{e}}_z$, and cooled evaporatively via forced RF evaporation, sweeping the RF frequency from 18 MHz to 2 MHz in 10 s. The magnetic trap was plugged by a tightly focused green beam at the center, providing a repulsive potential around the zero field point to prevent Majorana losses. Since the ^{40}K atoms were spin polarized and therefore non-interacting, they re-thermalized only due to interaction with ^{87}Rb atoms.

We then loaded the atoms into a crossed optical dipole trap, provided by a 1064 nm fiber laser, and continued evaporative cooling by slowly ramping down the dipole trap to trap frequencies of $(\omega_x, \omega_y, \omega_z)/2\pi = (39, 42, 124)$ Hz in the three spatial directions, while also turning off the quadrupole field. We then used adiabatic rapid passage (ARP) to transfer the ^{87}Rb atoms from the $|F = 2, m_F = 2\rangle$ state to the $|F = 1, m_F = -1\rangle$ absolute ground state via 6.8556 GHz microwave coupling (20.02 MHz from the zero field resonance) followed by a magnetic field sweep from -0.469 mT to -0.486 mT in 50 ms. This state was chosen to minimize spin changing collisions with ^{40}K atoms during any further evaporation [2]. We then briefly applied an on-resonant probe laser, ejecting any remaining ^{87}Rb atoms in the $F = 2$ manifold from the trap. We again used ARP to transfer the ^{40}K atoms into the $|F = 9/2, m_F = -9/2\rangle$ state by using a 3.3 MHz rf field and sweeping the bias magnetic field from -0.518 mT to -0.601 mT in 150 ms.

Following the state transfer, we had two versions of the protocol - one for approaching the Feshbach resonance from higher fields and one for approaching it from lower fields. For approaching the resonance from lower fields, we proceeded by ramping the bias magnetic field to 19.05 mT, turning on a 42.42 MHz RF field, and then ramping the bias field up and down by 0.28 mT in a sinusoidal fashion, decohering the ^{40}K state into an equal superposition of $|F = 9/2, m_F = -9/2\rangle$ and $|F = 9/2, m_F = -7/2\rangle$. For approaching the resonance from higher fields, the same was done at a bias field of 21.71 mT and an RF frequency of 112.3 MHz. The depolarization allowed the ^{40}K atoms to

interact and re-thermalize, allowing us to further evaporate in the dipole trap [6]. Since ^{87}Rb is heavier than ^{40}K , we were able to evaporate the ^{40}K atoms past the point where ^{87}Rb atoms were no longer suspended against gravity and had been completely removed. These hyperfine states of ^{40}K were then used to study their Feshbach resonance.

After evaporation, we ramped the bias field in a two-step fashion to the desired value B near the Feshbach resonance. We approached the field using a large pair of coils in Helmholtz configuration (0.19 mT/A) to bring the magnetic field to a setpoint 0.59 mT away from B . We held the atoms at this field for 100 ms to allow the eddy currents induced by the large coils to settle, and then used a lower inductance (smaller - 0.017 mT/A) set of Helmholtz coils to quickly change the field the remaining 0.59 mT. When approaching the resonance from below, we used the large coils to get the field to $B - 0.59$ mT and used the small coils to quickly get to the desired field, while for approaching from above the resonance, we used the large coils to get to $B + 0.59$ mT and then used the small coils to quickly get the field down to the desired value. This allowed us to study the resonance from both sides without the added losses associated with going through the resonance [4].

Once at the intended bias field, we split the cloud into two spatially overlapping components with opposing momenta and observed scattering as they moved through each other and separated. These counterpropagating components were created using an $8E_L$ deep near resonant ($\lambda_L=766.704$ nm) 1-d retro-reflected optical lattice, where $E_L = \hbar^2 k_L^2 / 2m_K$ is the lattice recoil energy and $\hbar k_L = 2\pi\hbar/\lambda$ is the recoil momentum. We rapidly pulsed this lattice on and off with a double-pulse protocol [7, 28]. The pulse sequence was optimized to transfer most of the atoms into the $\pm 2\hbar k_L$ momentum states. Since the initial Fermi gas had a wide momentum spread (in contrast to a BEC, which has a very narrow momentum spread), and the lattice pulsing is a momentum dependent process, not all the atoms were transferred into the target momentum states. We optimized our pulse times to minimize the atoms remaining in the zero momentum state. The optimized pulse times were 23 μs for the first pulse, 13 μs off interval, and 12 μs for the second pulse.

We then released the atoms from the trap and allowed 1 ms for the two opposite momentum states within the cloud to pass through each other, scattering on the way. For the data taken coming from below the Feshbach resonance, we then simply ramped down the field and imaged the atoms. For the data taken coming from above the Feshbach resonance, we ramped the field back up, retreating through the resonance if it had been crossed and thereby dissociating any molecules that were created, and then quickly ramped the field back down and imaged the atoms. We used a 40 μs imaging pulse with $I_0/I_{\text{sat}} \approx 0.6$ at the center of the probe laser.

The total time-of-flight, the time from the moment the atoms were released from the trap to when they were imaged, was $t_{\text{TOF}} = 6.8$ ms. In such an image, the observed atomic position is determined by the initial velocity upon release from the trap, along with the time-of-flight time t_{TOF} . Therefore, this technique measures the momentum and not the position distribution of the atoms.

Figure 8. An example of our absorption image after 6.8 ms time of flight. The 1-D lattice imparts momentum along $\hat{\mathbf{e}}_x$. The two large clouds on the left and right are the atoms in the $\pm 2k_r$ momentum orders that passed through each other unscattered. The smaller cloud in the center is the atoms that remained in the lowest band of the lattice after pulsing, and thus obtained no momentum. The thin spread of atoms around these clouds is the atoms that underwent scattering. This image was taken coming from below the Feshbach resonance at 20.07 mT. (a) Raw optical depth, (b) atomic column density obtained by comparing to simulated ODs , $\sigma_0 n^{\text{sim}}$

The magnetic fields produced by our coils were independently calibrated by rf-spectroscopy. We prepared ^{87}Rb atoms in the $|F = 1, m_F = -1\rangle$ state and illuminated them with an rf-field with some frequency ν_{rf} . We then set the bias field closely below the expected resonance point and ramped the bias field to variable settings, and used Stern-Gerlach imaging to find the point of equal population between the $|F = 1, m_F = -1\rangle$ and $|F = 1, m_F = 1\rangle$ state, with the largest population in $|F = 1, m_F = 0\rangle$. The field that produced the equal population splitting was on-resonant, and we used the Breit-Rabi formula to determine the resonant field value at ν_{rf} . We did this for several rf frequencies, and for each coil independently.

3.2. Methods

We first processed each image by comparing the observed ODs to simulations taking into account the recoil induced detuning as described in Sec. 2. An example of images before and after processing are shown in Fig. 8. To improve the signal and compensate for any shot to shot number fluctuations, we took 15 nominally identical images for each data point and averaged the processed images.

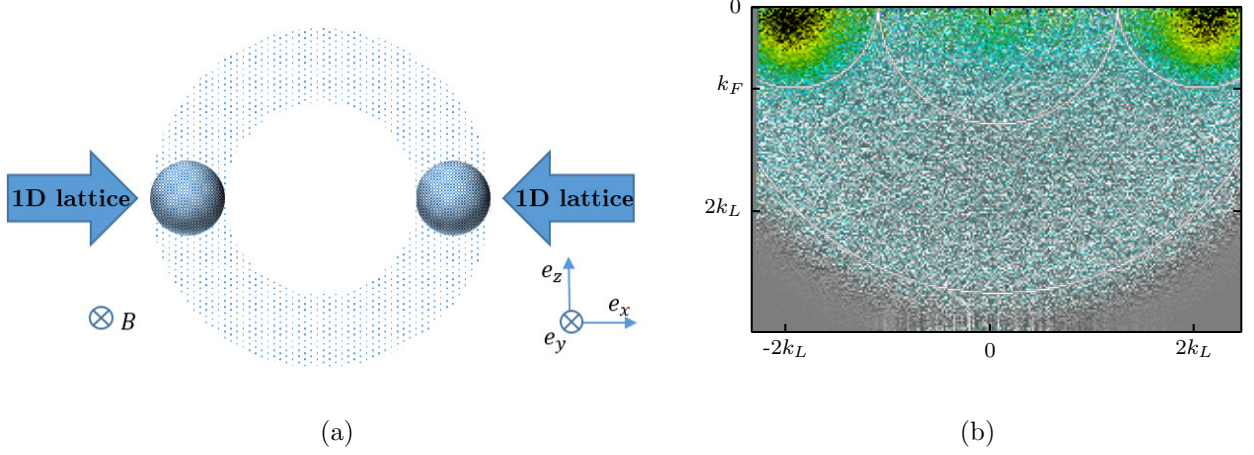

Figure 9. (a) Our experimental setup. After time of flight, the two clouds traveling along $\pm \hat{e}_x$ directions have separated and the atoms that underwent a single scattering event were evenly distributed in a scattering halo around the unscattered clouds. The 1-D lattice defined the axis of cylindrical symmetry. (b) Inverse Abel transformed image. The atoms within the Fermi momentum k_F of each unscattered cloud center are in the unscattered region and counted towards the total unscattered number. The atoms outside the radius $k_r - k_F$ but inside $k_r + k_F$ but outside the unscattered region are counted towards the number of single scattered atoms.

We counted the fraction of atoms that experienced a single scattering event as a function of the bias field. Single scattering events are easily identified, as two atoms that scatter elastically keep the same amplitude of momentum, but depart along an arbitrary direction. Therefore, an atom traveling at $2\hbar k_L$ to the right that collides elastically with an atom traveling at $-2\hbar k_L$ to the left will depart with equal and opposite momenta ($2\hbar k_L$) at an arbitrary angle, and in a time of flight image such atoms will lie in a spherical shell, producing the weak scattering halo pictured in Fig. 9a.

Absorption images captured the integrated column density along \hat{e}_z , a projected 2-D atomic distribution. To extract the radial dependence of the 3-D distribution from the 2-D image, we performed a standard inverse Abel transform. The inverse Abel transform assumes cylindrical symmetry, which was present in our case, with the axis of symmetry along \hat{e}_x , defined by the lattice. We thus obtained the atomic distribution as a function of r , the radial distance from the scattering center, and θ , the angle between r and symmetry axis \hat{e}_x , integrated over ϕ , the azimuthal angle around the x axis.

We then extracted the number of scattered atoms N_{scat} as a fraction of the total atom number N_{tot} for each bias magnetic field, as shown in Fig. 9b. The unscattered atom number was the number of atoms in the two unscattered clouds. The number of atoms that underwent a single scattering event was the number of atoms outside the Fermi radius of the unscattered clouds, but inside the arc created by rotating the Fermi momentum k_F around the original center of the cloud (white arcs in Fig. 9b). The atoms in the center region were not counted as they were originally in the zero

momentum state and could not contribute to the scattering halo under study.

We then deduced the resonant field value B_0 and width of the resonance Δ , the parameters in Eq. (1). Since we were in the low energy regime (the Fermi momentum was much smaller than one over the range of inter-atomic van der Waals interactions $k_F \ll 1/l_{vdW}$), the scattering cross-section was given by $\sigma = 4\pi a^2$.

The scattering cross-section σ gives the probability $P_{scat} = \sigma N/A$ that a single particle will scatter when incident on a cloud of atoms with a surface density of N/A , where A is the cross-sectional area of the cloud and N is the number of atoms in the cloud. In our case, each half of the initial cloud, with atoms number $N_{tot}/2$, is incident on the other half. Thus, the number of expected scattering events is $N_{scat} = (N_{tot}/2)\sigma(N_{tot}/2) = \sigma N_{tot}^2/4A$. Assuming A is constant for all our data, we can define a fit parameter $b_0 = 4\pi a_{bg}^2/4A$, where a_{bg} is the background scattering length adapted Eq. (1) to obtain the fit function

$$\frac{N_{scat}}{N_{tot}^2} = b_0 \left(1 - \frac{\Delta}{B - B_0}\right)^2 + C. \quad (14)$$

We found that our imaging noise skewed towards the positive, giving rise to a small background offset. We accounted for this in our fit by including a constant offset parameter C .

3.3. Results

Our final data is presented in Fig. 10. The red curve depicts a best fit of the model given in Eq. (14). The fit parameters we extracted were $\Delta = 1.0(1)$ mT, $B_0 = 20.247(2)$ mT, and $C = 90 \times 10^{-6}$. To obtain the fit, we used data taken by approaching the resonance from above for points above where we expected the resonance to be and data taken approaching the resonance from below for points below. We also excluded from the fit data points very near the resonance, as there the assumption $\sigma\rho \ll 1$, where ρ is the atom number per unit area, is no longer valid and the problem must be treated hydrodynamically. The error bars on the fitted data were obtained solely from photon shot noise of both absorption images propagated through our analysis. The accepted values for the ^{40}K s-wave Feshbach resonance for the $|9/2, -9/2\rangle$ and $|9/2, -7/2\rangle$ states are $B_0 = 20.210(7)$ mT and $\Delta = 0.78(6)$ mT [22]. The difference in our measurement may be a result of scattering with atoms that did not receive a momentum kick from the lattice pulsing, a process that was not taken into account by our analysis, or the impact of multiple scattering events.

4. Conclusion

We studied the effects of recoil-induced detuning effects on absorption images and found an optimal imaging time of $\approx 40 \mu\text{s}$ for ^{40}K atoms for noise minimization after corrections. We use these results to observe s-wave scattering halos of the Fermi gas around the ≈ 20.2 mT Feshbach resonance and directly verified the resonance location

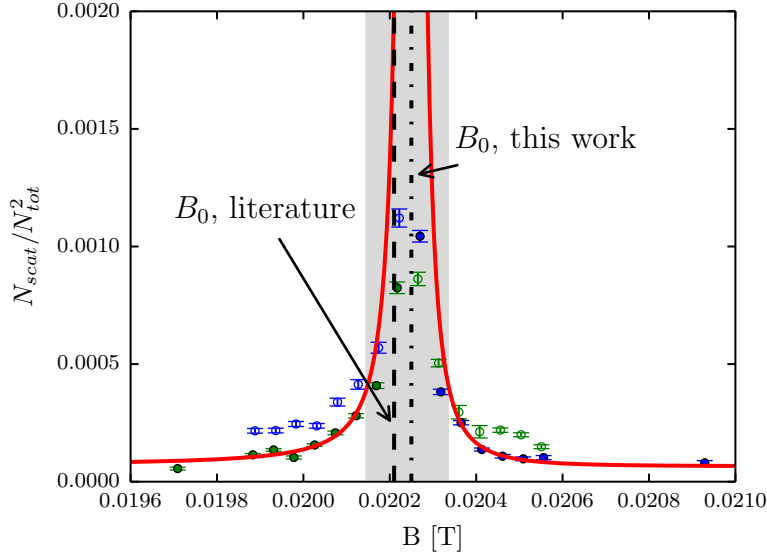

Figure 10. Normalized scattered population plotted versus bias field B . Green dots represent data taken coming from below the resonance, and blue dots represent the data taken coming from above the resonance. The red curve depicts the best fit, where data coming from above the resonance was used above the resonance and data coming from below the resonance was used below the resonance to create the fit; the unused data points are indicated by hollow dots. The regime where the scattering length is likely large enough for the atoms to behave hydrodynamically is shaded in gray, and data points in that area were also excluded from the fit. Values for the resonant field B_0 from literature and as found in this work are indicated.

and width. Our analysis can be used in any absorption imaging application where signal to noise optimization is critical.
